Abstract
The time-varying natural rate of interest and output and the implied medium-term inflation target for the US economy are estimated over the period 1983-2005. The estimation is conducted within the New-Keynesian framework using Bayesian and Kalman-filter estimation techniques. Employing the model-consistent estimate of the output gap, we get a small weight on the backward-looking component of the New-Keynesian Phillips curve – similar to studies which use labor share of income as a proxy for marginal costs (e.g., Gali et al., 2001, 2003). The turning points of the business cycle are nevertheless broadly consistent with those of CBO/NBER. We find considerable variation in the natural rate of interest while the inflation target has been close to 2% over the last decade.

JEL-codes: C51, E32, E37, E52.

Keywords: Natural rate of interest, natural rate of output, New-Keynesian model, inflation target.

1 Introduction

The New Keynesian theory as developed Goodfriend and King (1997), Rotemberg and Woodford (1997), McCallum and Nelson (1999a) and others, and with policy implications extensively explored in Clarida et al. (1999) and Woodford (2003), has become the leading framework for the analysis of monetary policy. This theory honors the proposition that monetary policy affects only nominal variables in the long run and that the steady-state inflation rate can be governed by monetary policy. Moreover, it assumes that the central bank implements its policy through the setting of the short-term interest rate. Monetary policy influences decisions about real magnitudes due to prices not being fully free to adjust to shocks (price rigidities). The overriding objective of monetary policy is to alleviate the effects of these rigidities while keeping inflation expectations close to a target rate of inflation.

An important point of reference for the policymaker is therefore how the economy would have developed had prices been without rigidities and instead fully flexible. We refer to the rate of interest and the level of output in such an equilibrium as the natural rates of interest rates and the natural level of output (see Woodford, 2003). Consistent with this view, the strategy of monetary policy is often formulated in terms of deviations from these natural rates, that is, in terms of the interest rate gap and the output gap respectively. The well-known Taylor rule (Taylor, 1993) provides an illustration. Under the Taylor rule, the central bank raises the interest rate relative to the natural rate of interest if either inflation deviates from the inflation target and/or output deviates from the natural rate of output. In steady state, where there is no need for monetary policy to respond to shocks, the interest rate equals the natural rate. For these reasons, the natural rates are important indicators for the setting of the policy instrument and the characterization of a neutral monetary policy stance.
The main objective of this paper is to present a simple framework in which to derive the natural rates within a New Keynesian model setting. Using US data and Bayesian estimation and Kalman filtering techniques, we derive plausible time-varying estimates of the natural rates and the corresponding interest rate- and output gaps. Previous studies on the topic include the seminal paper by Laubach and Williams (2003) who use the Kalman filter to estimate the natural rate of interest and the output gap. Their model, however, specify the natural rates within a reduced form system devoid of forward looking elements. In this regard, our paper is more related to the recent unobserved components study of Basistha and Nelson (2007) which acknowledge that inflation may be dependent on expected future inflation. They derive the output gap assuming that inflation depends on (survey measures of) expected future inflation as well as past inflation rates and the output gap. We extend on their contributions by deriving the estimates in a way that is consistent with New Keynesian theory restrictions and furthermore allowing inflation expectations to be rational and theory consistent.

Another facet of the contribution of this paper is the allowance of the possibility of a time-varying inflation target. US inflation history is difficult to reconcile with a constant inflation target. In this regard, our approach is similar to that of Ireland (2007). While we, however, assume that the inflation target reflects a preference of the monetary policymaker and is unrelated to the state of the economy, Ireland assumes that the inflation target is dependent on some of the shocks to private sector behavior. Our conclusions regarding the evolution of the inflation target are nevertheless similar.

A third novelty of our approach is that is does not require detrending of the data prior to analysis (using for instance the HP-filter) or making output stationary by deflating by a trending variable (for instance by assuming that total factor productivity follows a

---

1The idea builds on the papers by Watson et al. (1997) and Gordon (1998), among others, that estimate the natural rate of unemployment (NAIRU) using the Kalman filter.
trend stationary process), as has been common practice in many recent DSGE analysis, including Edge et al. (2005), Juillard et al. (2005) and Smets and Wouters (2003, 2007) who also estimate the natural rates.\footnote{A recent exception is Juillard et al. (2006). They allow for a more general stochastic process where there could be both temporary changes in the growth rate of total factor productivity as well as autocorrelated deviations from steady state.}

An important empirical finding is that inflation is primarily a forward-looking process. By allowing inflation to have both forward-looking and backward-looking components, using a hybrid New-Keynesian Phillips curve, data prefers a forward-looking specification. Although this is the common conclusion in studies which use labor’s share of income as a proxy for marginal costs (see Galí et al., 2001, 2003), it is not common finding when the output gap is the proxy. Interestingly, after accounting for the time-varying inflation target and natural rate of interest, a model-consistent estimate of the output gap shares some of the same properties as labor’s share of income in representing marginal costs. This conveniently suggests that the approach of studying monetary policy within the small and simple model framework with inflation, output gap and the interest rate, as advocated in Woodford (2003), seems sensible.

The remainder of this paper is organized as follows. In Section 2 we present the New Keynesian framework. Section 3 presents the estimation framework and results. In Section 4 we provide some concluding remarks.

2 The New Keynesian Framework

The New Keynesian framework\footnote{See Goodfriend and King (1997), Rotemberg and Woodford (1997), Rotemberg and Woodford (1999), McCallum and Nelson (1999b) and Clarida et al. (1999).} assumes that firms operate in monopolistic competitive markets and production is constrained by aggregate demand. Prices are assumed to be sticky and consequently do not move instantaneously to movements in marginal costs. Due to the price stickiness, the central bank affects aggregate demand through its influence
on real interest rates. By lowering real interest rates, the central bank induces higher aggregate demand, marginal costs and prices than would otherwise materialize. As noted above, the natural rate of interest rate can be regarded as the neutral stance of monetary policy - the real interest rate that produces zero output gap and stable inflation.

In estimating the natural rates, we build on the economic structure provided by the New Keynesian framework. The basic model is extended with external habit formation in consumption (Fuhrer, 2000) and a hybrid New-Keynesian Phillips curve that allows for both forward-looking and backward-looking elements. This set up is rationalized by the Calvo (1983) framework with some of the firms setting prices in accordance to an indexation scheme (Christiano et al., 2005) or in accordance with some rule-of-thumb (Galí and Gertler, 1999).

The approach remains nevertheless conservative regarding the extent of the economic structure regarding production technology and the structure of the labor market imposed in estimation. This reduces the approach’s rigor at the gain of not being tied up to a particular description of production technology which may bias the result if incorrect. Specifically, we allow the natural rate of output to follow exogenous processes and in this regard, the paper draws on the literature on structural time-series estimation, see e.g. Harvey (1989).

2.1 Aggregate demand

We assume that the economy consists of a representative household that lives forever and maximizes expected utility given by

\[
U = E_t \sum_{i=0}^{\infty} \left( \frac{1}{1 + \delta} \right)^i \left[ \frac{1}{(1 - \sigma)} \left( \frac{C_{t+i}V_{t+i}}{H_{t+i}} \right)^{(1-\sigma)} \right],
\]
subject to the intertemporal budget constraint given by

$$C_t + \frac{M_t}{P_t} + B_t = \left(\frac{W_t}{P_t}\right) N_t + \frac{M_{t-1}}{P_t} + I_{t-1} \frac{B_{t-1}}{P_t} - T_t \frac{B_t}{P_t} + \Pi_t.$$ 

$\delta$ is the discount rate, $\sigma$ is the intertemporal elasticity of substitution and $C$ is an CES index of consumption goods. $V$ is a consumption preference shock. The consumer is also assumed to have preferences over money and leisure, but for simplicity, these are not explicitly modeled.

The consumer can either hold money ($M$) or bonds ($B$) as a store of wealth. Money yields utility (not modeled) whereas bonds yield a gross risk-free return of $I_t$ in every period. Consumption preferences are subject to a shock $V_t \equiv (1 - v_t)$ where

$$v_t = \rho_v v_{t-1} + \tilde{v}_t$$

and $\tilde{v}_t$ is a white-noise shock. $H_t$ represents external habit persistence. We allow habit persistence to be of order 2 and specify as follows

$$H_t = C_t^{\gamma_1} C_{t-2}^{\gamma_2}$$

where $\gamma_1$ and $\gamma_2$ are habit parameters. This more general setup allows agents to form habits with respect to the changes in as well as the level of consumption.

The first-order condition for the solution to the problem implies the consumption Euler equation

$$\left(\frac{C_t V_t}{C_{t-1}^{\gamma_1} C_{t-2}^{\gamma_2}}\right)^{1-\sigma} \frac{1}{C_t} = \left(\frac{1}{1 + \delta}\right) I_t E_t \left(\frac{C_{t+1} V_{t+1}}{C_t^{\gamma_1} C_{t-1}^{\gamma_2}}\right)^{1-\sigma} \frac{1}{C_{t+1} P_{t+1}}.$$ (2)
Taking the logarithm of the Euler equation and using the resource constraint, we have

\[ y_t = \frac{\sigma}{A} E_t y_{t+1} + \frac{(\gamma_1 - \gamma_2) (\sigma - 1)}{A} y_{t-1} + \frac{\gamma_2 (\sigma - 1)}{A} y_{t-2} - \frac{1}{A} (i_t - E_t \pi_{t+1} - \delta) + \frac{(\sigma - 1)}{A} (v_t - E_t v_{t+1}), \]

where \( A \equiv \sigma + \gamma_1 (\sigma - 1) \) and \( \pi_t \) is quarterly inflation at an annual rate. A small letter denotes the log of the corresponding capital letter variable.\(^4\)

Note that due to dynamic homogeneity, we can write the aggregate demand schedule (3) as

\[ \Delta y_t = \frac{\sigma}{\gamma_1 (\sigma - 1)} E_t \Delta y_{t+1} - \frac{\gamma_2}{\gamma_1} \Delta y_{t-1} - \frac{1}{\gamma_1 (\sigma - 1)} (i_t - E_t \pi_{t+1} - \rho) + \frac{1}{\gamma_1} (v_t - E_t v_{t+1}). \]

### 2.2 Aggregate supply

Aggregate supply is represented by the hybrid Phillips curve as

\[ \pi_t = \mu E_t \pi_{t+1} + (1 - \mu) \sum_{j=1}^{4} \alpha_j \pi_{t-j} + \zeta m_c + \varepsilon_t \]

where \((1 - \mu)\) is the weight on the backward-looking component and \(m_c\) is marginal costs as of time \(t\). As in Rudebusch (2002a, b), we allow for a lag structure on past inflation to match the dynamics of inflation at the quarterly frequency. Furthermore, we impose dynamic homogeneity, i.e., that \(\alpha_4 = 1 - \alpha_1 - \alpha_2 - \alpha_3\).\(^5\) We assume that log marginal

\(^4\)Note that we have for simplicity ignored Jensen’s inequality and used first-order Taylor approximations, implying \(\ln E(1 + x) = E \ln(1 + x) = Ex\).

\(^5\)Although we do not provide any microfoundations for these lags, we postulate that these lags will follow from the rules-of-thumb framework of pricing of Gali and Gertler (1999) given that rule-of-thumb allows for longer lags.
costs are linear in log deviation of output from its natural rate, i.e.,

\[ mC_t = \tilde{\gamma} (y_t - y^n_t), \]

where \( y^n_t \) is the natural rate of output. By defining the deviation of output from the natural rate as the output gap, \( x_t \equiv y_t - y^n_t \), we can write the Phillips curve as

\[ \pi_t = \mu \hat{E}_t \pi_{t+1} + (1 - \mu) \sum_{j=1}^{4} \alpha_j \pi_{t-j} + \kappa x_t + \varepsilon_t, \tag{5} \]

where \( \kappa \equiv \zeta \tilde{\gamma} \). The natural rate of output is given exogenously by the process

\[ \Delta y^n_t = \nu + \omega_t \tag{6} \]

where \( \nu \) is the unconditional expected growth rate of output and \( \omega_t \) is an AR(1) shock to the growth rate\(^6\)

\[ \omega_t = \phi \omega_{t-1} + q_t. \tag{7} \]

The output gap follows the process

\[ x_t = x_{t-1} + \Delta y_t - \Delta y^n_t. \tag{8} \]

---

\(^6\)The shock \( q \) is best thought of as representing variations in productivity and preferences that influence the marginal rate of substitution between consumption and leisure. Neither sources is modeled explicitly here.
2.3 Monetary policy

The monetary authority is setting the interest rate in accordance with a dynamic Taylor rule as

$$i_t = \psi i_{t-1} + (1 - \psi) (i^n_t + \theta_{\pi} (\bar{\pi}_t - \pi^T_t) + \theta_{x}x_t) + u_t,$$  \hspace{1cm} (9)

where $\psi$ measures the smoothing in the interest rate setting. $i^n_t$ is the nominal natural interest rate (defined below) and

$$\bar{\pi}_t \equiv \frac{1}{4} \sum_{j=0}^{3} \pi_{t-j}$$

is the four-quarter inflation at an annual rate. We assume that the intermediate-run inflation target evolves according to

$$\pi^T_t = (1 - \rho_{\pi}) \pi^* + \rho_{\pi} \pi^T_{t-1} + \xi_t,$$  \hspace{1cm} (10)

where $\pi^*$ is the steady-state inflation rate (or long-run inflation target) and $\xi_t$ is an AR(1) shock to the inflation target, following

$$\xi_t = \rho_{\xi} \xi_{t-1} + \kappa_t.$$  \hspace{1cm} (11)

2.4 The natural interest rate

The process for the natural nominal rate of interest can be found by replacing output and the interest rate in equation (3) with the natural rates and then solving for the interest
rate, i.e.,

\[ y_t^n = \frac{\sigma}{A} E_t y_{t+1}^n + \frac{(\gamma_1 - \gamma_2)(\sigma - 1)}{A} y_{t-1}^n \]

\[ + \frac{\gamma_2 (\sigma - 1)}{A} y_{t-2}^n - \frac{1}{A} (i_t^n - E_t \pi_{t+1} - \delta) + \frac{(\sigma - 1)}{A} (v_t - E_t v_{t+1}), \]

or

\[
\Delta y_t^n = \frac{\sigma}{\gamma_1 (\sigma - 1)} E_t \Delta y_{t+1}^n - \frac{\gamma_2}{\gamma_1} \Delta y_{t-1}^n
\]

\[ - \frac{1}{\gamma_1 (\sigma - 1)} (i_t^n - E_t \pi_{t+1} - \delta) + \frac{1}{\gamma_1} (v_t - E_t v_{t+1}). \]

and isolating for the natural interest rate

\[ i_t^n = \delta + E_t \pi_{t+1} + \sigma E_t \Delta y_{t+1}^n - \gamma_1 (\sigma - 1) \Delta y_t^n - \gamma_2 (\sigma - 1) \Delta y_{t-1}^n \]

\[ + (\sigma - 1) (v_t - E_t v_{t+1}). \]

The natural real interest rate is then found from the Fisher equation as

\[ r_t^n \equiv i_t^n - E_t \pi_{t+1}. \] (15)

The output gap process can be expressed as a function of the natural interest rate by subtracting equation (12) from equation (3) which gives

\[ x_t = \frac{\sigma}{A} E_t x_{t+1} + \frac{(\gamma_1 - \gamma_2)(\sigma - 1)}{A} x_{t-1} \]

\[ + \frac{\gamma_2 (\sigma - 1)}{A} x_{t-2} - \frac{1}{A} (i_t - i_t^n) \]

where the natural rate of interest is given in equation (14) above.
3 Estimation

We estimate the parameters of the model comprising of equations (1), (4), (5), (6), (7), (8), (9), (10) and (11) using Bayesian methods and the Kalman filter. The focus of the analysis will be on the estimation of the natural real rate of interest and the output gap.

The use of Bayesian methods to estimate DSGE models has increased over recent years, in a variety of contexts, see An and Schorfheide (2006) for a recent evaluation. The focus is on methods that are built around a likelihood function, typically derived from a DSGE model (see, e.g., Adolfson et al., 2005). With sensible priors, Bayesian techniques offer a major advantage over other system estimators such as maximum likelihood, which in small samples can often allow key parameters to wander off in nonsensical directions.

3.1 Data

We estimate the model laid out in the previous section using U.S. quarterly time series for three variables: real output, inflation and interest rates. The sample period is 1983q1 to 2005q4. The period covers the last part of the Volcker period and the major part of the Greenspan period. The choice of periods follows from the assumption that these two Chairmen shares approximately the same dislike for inflation. The monetary policy regime is therefore roughly constant over the sample period. We use the quarterly average daily readings of US 3-month deposit rates as the relevant nominal interest rate. For real output and inflation we use real GDP and the CPI, all items, for total USA. GDP and CPI are seasonally adjusted by their original source (OECD). We treat inflation, output growth, and the nominal interest rate as stationary, and express them in deviations from their sample mean. Note that all changes are measured at an annual rate. Inflation, output and 3-month deposit rates are plotted in Figure 1.1 in the appendix.
3.2 Parameter estimation

As is well known from Bayes’s rule, the posterior distribution of the parameters is proportional to the product of the prior distribution of the parameters and the likelihood function of the data. This prior distribution describes the available information prior to observing the data used in the estimation. The observed data is then used to update the prior, via Bayes theorem, to the posterior distribution of the model’s parameters.

To implement the Bayesian estimation method, we need to be able to evaluate numerically the prior and the likelihood function. Then we use the Metropolis-Hastings algorithm to obtain random draws from the posterior distribution, from which we obtain the relevant moments of the posterior distribution of the parameters.

More specifically, the model is estimated in two steps in Dynare-Matlab. In the first step we compute the posterior mode using 'csminwel’, an optimization routine developed by Christopher Sims. We use the first three years of the full sample 1983q1 to 2005q4 to obtain a prior on the unobserved state, and use the subsample 1986q1 to 2005q4 for inference. To calculate the likelihood function of the observed variables we apply the Kalman filter. In the second step, we use the mode as a starting point to compute the posterior distribution of the parameters and the marginal likelihood by simulations of the Metropolis-Hasting (MH) algorithm (see Schorfheide, 2000, for details). The debugging features of Dynare are used to determine if the optimization routines have found the optimum and if enough draws have been executed for the posterior distributions to be accurate. Having estimated the parameters, they can then be used to construct the natural rates of interest rates and output.

3.3 Prior and posterior distributions of the estimated parameters

The Bayesian estimation technique allows us to use prior information from previous micro
and macro based studies in a formal way. Table 1 below summarizes the assumptions for the prior distribution of the estimated parameters and structural shocks. In the first three columns, the list of structural coefficients with their associated prior mean, standard deviations and distribution are shown. Following standard conventions we use Beta distributions for parameters that fall between zero and one, (inverted) gamma (invg) distributions for parameters that need to be constrained to be greater than zero and normal (norm) distributions in other cases. For some of the parameters, the distribution is constrained further, as indicated in column four (‘support’).

The next three columns indicate the posterior mean and the associated 95 percent confidence interval. Starting with the Phillips curve, we provided a prior for $\mu = 0.50$ that put equal weight on the forward-looking and backward-looking components with a large standard deviation providing a rather diffuse prior. This choice is rationalized by the fact that the literature has suggested estimates in the whole zero-unity interval. We wanted data to determine this coefficient without pushing it in either direction. In the estimation, $\alpha_1, \alpha_2, \alpha_3$ and $\alpha_4$ were restricted to sum to one (with $\alpha_4$ determined by this identity). However, since we do not have a strong prior on their magnitudes, we give them the same weight with the standard deviation set to 0.1. $\kappa$ was estimated at 0.089 which is not far from the estimate of 0.13 obtained by Rudebusch (2002a,b) who used CBO estimate of the output gap.

We find that the Phillips curve is primarily forward looking, it has nevertheless a non-negligible weight on the backward-looking component, with $(1-\mu)$ just below 0.4. This is consistent with the estimates of the New Keynesian Phillips curve found when using labor’s share of income as the proxy for marginal costs as opposed to using detrended output. Our results are consistent with the estimation results in Gali et al. (2003, 2005) using a full information, system estimation. We find this result interesting because it

sugests that the output gap may proxy marginal costs on par with labor’s share of income once we use a model-consistent estimate of the output gap. Further, our results also support that monetary policy can be studied within the simple two-equation model framework which explains the development of inflation and the output gap conditional on the policy instrument (as suggested by Clarida et al. (1999) and Woodford (2003)).

Regarding the expectational IS curve, we find that our prior on the intertemporal elasticity of substitution $\sigma = 2$ is well within the range of the estimates in the literature. The posterior has increased somewhat from the prior, although not significantly so (posterior mean equals 2.05). Moreover, the preference shocks display a high degree of persistence, with a coefficient of $\rho_v = 0.95$. In addition, the habit parameters $\gamma_1$ and $\gamma_2$ are restricted to lie between zero and one, with the prior for $\gamma_1$ being the largest, assuming more habit from the immediate past. However, we choose a large standard deviation of 0.2 that provides us with a fairly diffuse prior. The second-order habit persistence is well accounted for in data, as both $\gamma_1$ and $\gamma_2$ turn out to be above, yet close to 0.5. Finally, the prior for the annual discount rate $\delta$ is set to 0.04, reflecting a quarterly discount factor of 0.99. Rather surprisingly, we find that data push the annual discount rate from the prior of four percent to 1.6 percent.

The prior for the equilibrium natural output growth rate is set equal to the (annual) growth rate in the model (3 percent), with the posterior mean estimated to $\nu = 0.029$.

The data seems to support a dynamic Taylor rule specification of monetary policy reasonably well. The monetary policy shock has standard deviation of 0.024. Moreover, the weight on inflation and output gap is deviating only marginally from the priors and what Taylor (1993) suggested as likely coefficients (0.5). There is a pronounced gradual adjustment of the interest rate with $\psi = 0.83$. Finally, we calibrate the steady-state inflation rate $\pi^*$ to be equal to steady state inflation. The results seems to indicate fairly persistent movements in the medium-run inflation target ($\rho_\pi = 0.85$), with also rather

persistent shocks to this process (ρχ = .80). The latter suggest that movements in the medium-run inflation target is done gradually over time.

3.4 Error variance decomposition and impulse responses

Table 2 shows the decomposition of the unconditional variance. Some interesting observations can be made from the table. We first note that the main drivers of inflation variations are the cost-push and inflation-target shocks. These shocks account for about 80% of the variation in inflation. If the central bank adheres to an inflation-targeting loss specification with the loss function having inflation and output gap variations as the two arguments (see Svensson (1997) and Clarida et al. (1999)), efficiency in policymaking requires that inflation should be driven only by cost-push and inflation-target shocks. The ratio is high and can be taken as an indication of efficiency in policymaking. However, by the same logic, the central bank should neutralize the impact of preference shocks on both the output gap and inflation. This does not seem to be the case. Although the Taylor rule has allowed strong responses to the preference shocks as they can explain more than 80% of the variation in the interest rate, preference shocks have still influenced inflation and, in particular, the output gap to a large extent. Hence, the estimated Taylor rule does less well in insulating the economy from this type of shock.

The natural real interest rate is driven mainly by preference shocks. Shocks to the
natural rate of output play only a minor role in explaining the variation observed. This partly reflects the fact that the standard deviation preference shocks is large relative to the standard deviation of shocks to the natural rate of output.

The impulse response functions are shown in the appendix. None of these responses deviate from what we understand as conventional thinking, although the responses to some of the shocks seem to be rather fast (preference shocks in particular). The impulses from the monetary policy shock correspond well with results generated from VARs: For a positive shock to the interest rate, the output gap falls on impact and inflation reacts with a lag. The short-term interest rate falls relatively quickly and enters a period in which the policymaker corrects for the shock. Finally, a shock to the medium-run inflation target raises inflation expectations and the current inflation rate on impact due to the expectations channel. The nominal interest rate increases, but the real interest rate falls and creates a temporary increase in the output gap which again increases inflation. Inflation peaks after 5 quarters and is then brought slowly back to the steady-state rate of inflation over a 5–7 years period. Hence, the medium-term is relatively long, approximately equal to the average business cycle. This gives some indication of the medium-term inflation target being used as an instrument to smooth output as a result of pursuing a constant inflation target over the business cycle.

3.5 The estimated variables

The smoothed output gap, the medium-run inflation target and the nominal and real natural interest rates are shown with 95% confidence intervals in Figure 1. Furthermore, Figure 2 shows the smoothed natural rate of output and the natural real interest rate plotted with actual output and the real interest rates respectively, as well as the real interest rate gap ($r - r^n$) and the estimated inflation gap ($\bar{\pi}_t - \pi^T$).

The output gap estimates suggest two recessions over the sample period: the first one
The figures show the estimated smoothed variables over the sample period.

with a trough in 1991 and the other with a trough in 2001/2002. The recessions are of approximately the same order of magnitude, suggesting a deviation of output from the natural rate of output of approximately 5%. The recessions correspond to periods with large positive interest-rate gaps (see Figure 2). Further, as will be discussed in more detail below, the dates for the turning points and the length of the business cycles do not seem inconsistent with NBER/CBO estimates.

The sample average CPI inflation over the period is 3.3%. The estimated medium-run inflation target suggests that the mild run-up of inflation in the late 1980s, due to
From the top-left panel and moving clockwise: The panels show the natural rate of output and the real rate with their observed variables, the inflation gap and the interest rate gap.

a positive output gap, was partly accommodated by an increase in the inflation target over the period, see Figure 1. The reduction in the rate of inflation of the first part of the 1990s, accompanied by the recession in the same period, can partly be explained by a reduction in the inflation target. From 1994 to the end of the sample, the medium-run inflation target is estimated to be around 2% with a confidence band of about ±1 p.p.

For most of the period, the inflation target is significantly above zero. The inflation gap (see Figure 2) suggests that for the major part of the 1990s and the period after 2002, inflation has in general been above the medium-term inflation target, and therefore has exerted an upward pressure on interest rates.

The estimate of the natural real interest rate shows considerable variation over the period – varying between −3% and 6%. The variation in the natural real interest rate
is in periods greater than the equivalent real interest rate. This is also found in the DSGE study of Edge et al. (2005), but not by Laubach and Williams (2003) where the natural interest rates appear as smoothed interest rates. Here, the natural rate follows instead from the stochastic processes governing the preference shocks and shocks to the natural rate of output (see equations (14) and (15)). These processes which determine the interest rate under the assumption of flexible prices are unaffected by the potential smoothing of interest rates done by the central bank in the sticky-price equilibrium. \(^8\) Moreover, the mode of the natural rate of interest is in the range 3 – 4% which does not seem unreasonable for the average real interest rate. The average natural interest rate is remarkably stable over the period 1994-2000 where the variation is in the region ±1p.p. This is a result also found by Edge et al. (2005). The recession of the first half of 2000s imply negative real interest rates for this period, suggesting a rather expansionary monetary policy that would have been needed in order to keep aggregate demand equal to the natural rate of output.

It has been relatively common to estimate monetary policy reaction functions conditional on the natural rate of interest being equal to a constant plus the inflation rate. The relatively large variation in the natural interest rate suggests that the estimates could be severely biased if the central bank is not taking account of the time-varying nature of the natural rate of interest when setting interest rate. In particular, the high degree of persistence in the natural rate in then likely to bias the coefficient on the past interest rate upwards. Moreover, failing to take account of the interdependence between the output gap and natural interest rates (estimates) may also bias the estimates.

With high volatility in the natural rate of interest, a “neutral” monetary policy stance

---

\(^8\)By the same logic, there is nothing that ensures that the evolvement of the natural rate of output is smoother than output itself. Woodford (2001, p.234) notes “In theory, a wide variety of real shocks should affect the growth rate of potential output[...] [T]here is no reason to assume that all of these factors follow smooth trends. As a result, the output-gap measure that is relevant for welfare may be quite different from simple detrended output.”
requires considerable changes in the interest rate. If the policymaker nevertheless regards the natural rate of interest as a constant, policy is likely to induce inefficient movements in inflation and output.

Some readers may object to the arguments by claiming that interest rates should be smoothed over time and for this reason the variability in the natural rate should largely be ignored. We claim that such an argument mixes up two things. Interest rate smoothing can be welfare-enhancing (see Woodford, 1999) in its own right due to its impact on private sector expectations. But optimal smoothing of interest rate does not imply the removal of some arguments over which the smoothing should be done. While the interest rate may be more volatile if responding to the natural interest rate, the benefits of interest rate smoothing can still be extracted.

...tive measures of the gap previously found in the literature. Figure 3 compares our measure of the output gap (BLM henceforth) to 
\(i\) the output gap derived from an updated version (2006) of Laubach and Williams (2003) (LW henceforth)\(^9\), \(ii\) the two sided output gap estimate of Basistha and Nelson (2007) (BN henceforth)\(^10\), \(iii\) the Congressional Budget Office (CBO) estimate of potential output as well as \(iv\) the Hodrick Prescott filtered output gap, with \(\lambda = 1600\) (HP henceforth)\(^11\). Tables 3 and 4 finally show respectively the correlation and the concordance (i.e., the time proportion that the cycles of two series spend in the same phase, see McDermott and Scott (2000))\(^12\) between the different estimates.

Our output gap series is picking the major NBER recession periods (of 1991 and 2001) efficiently. The gap is also broadly consistent with that of the other gaps, although there are notable differences. The differences are hardly surprising given that our estimate is consistent with a rational expectations forward-looking Phillips curve, whereas the others are not. Our estimate has the highest volatility and the smallest persistence of the series.

\(^9\)We thank John Williams for providing us with the updated simulation results.

\(^10\)Their output gap series was downloaded from [http://www.be.wvu.edu/divecon/econ/basistha/gap.htm](http://www.be.wvu.edu/divecon/econ/basistha/gap.htm).

\(^11\)The Hodrick Prescott method is a univariate statistical method designed to extract the low frequency component of a time series. Lambda penalizes the variation in the trend, and is determined a priori. Lambda= 1600 is commonly used in many internationally studies.

\(^12\)The measure of concordance is useful when the focus of the analysis is on the sign of the gap and not necessarily its magnitude.

Our Phillips curve allows for longer lags and this implies that, for a given value of \( \kappa \), the output gap needs to move more in order to have the same effect on inflation. The high degree of inflation persistence in the Phillips curve also imply that the needed persistence in the output gap is lower in order to explain the observed persistence in the inflation. Inflation is also more responsive to persistent changes in the output gap due to the large coefficient on future expected inflation in the Phillips curve. In order for the model to match inflation dynamics and volatility, the output gap then needs to be somewhat less persistent compared to a situation with a smaller forward-looking term in the Phillips curve. The deviations from the other series are likely to be attributable to the differences needed for the output gap to better reflect underlying marginal costs, as discussed above.

The differences show up in the measures of correlation. Table 3 indicates that there is modest degree of co-movement, with correlation coefficients varying around 0.5. The lowest correlation is found between our estimate (BLM) and that of BN.\(^{13}\) This is partly explained by the early 1990s, where all the output gaps except the BN output gap increase, with our measure suggesting a pronounced peak in 1994. Our estimate of the natural rate of interest rose sharply over the period 1993-1995 and the interest rate gap became negative (ref. Table 2). An expansionary monetary policy contributed to the output gap peak. The measures of concordance in the output gap, stated in Table 4, are slightly larger than the correlation coefficient for the alternative estimates. This implies that

\(^{13}\)In fact, the BN gap displays low correlation with all the other gaps as well.
the estimates differ more in their sizes than their phases, that is, the different methods
tend to pick the same phase for their respective output gap estimate. This is important
information for Central Banks that may care more of the sign of the gap rather than its
absolute magnitude.

4 Concluding remarks

This paper provides estimates of the natural real interest rate, the output gap and the
implicit inflation target for the US economy. The inflation target since 1994 has been
remarkably stable around 2 percent. The natural real interest rate has, however, been
varying a lot. The assumption often made in the monetary policy literature that the
natural real interest rate is exogenous or even constant, might be very misleading and
biasing the results. For the conduct of monetary policy, acknowledging the variation in
the real interest rate and conducting policy in accordance with it, seems to be important.

By estimating the hybrid New-Keynesian Phillips curve with a model-consistent es-
timate of the output gap, we find that the structure of the curve is very similar to that
found by estimating the Phillips curve with the labor share of income as a proxy for
marginal costs. The debate whether it is the output gap or the labor share of income
that provide the best proxy for marginal costs, may therefore be misleading. The paper
suggests that the output gap might represent marginal costs on par with labor’s share
of income once a model-consistent estimate of the output gap is used instead of ad-hoc
estimates, e.g. detrended (HP-filtered) output. If the output gap can be taken as a good
proxy for marginal costs, our results strengthen the idea that a simple two-variable sys-
tem in inflation and the output gap (see, Clarida et al. (1999) and Woodford (2003)) can
capture the effects of monetary policy on the private sector.
